ABSTRACT

Quad Flat No Leads (QFN) package designs receive more and more attention in electronic industry nowadays. This package offers a number of benefits including (1) small size, such as a near die-sized footprint, thin profile, and light weight; (2) easy PCB trace routing due to the use of perimeter I/O pads; (3) reduced lead inductance; and (4) good thermal and electrical performance due to the adoption of exposed copper die-pad technology. These features make the QFN an ideal choice for many new applications where size, weight, electrical, and thermal properties are important. However, adoption of QFN often runs into voiding issues at SMT assembly. Upon reflow, outgassing of solder paste flux at the large thermal pad has difficulty escaping and inevitably results in voiding. It is well known that the presence of voids will affect the mechanical properties of joints and deteriorate the strength, ductility, creep, and fatigue life. In addition, voids could also produce spot overheating, lessening the reliability of the joints. This is particularly a concern for QFN where the primary function of thermal pads is for heat dissipation. Thermal pad voiding control at QFN assembly is a major challenge due to the large coverage area, large number of via, and low standoff. Both design and process were studied for minimizing and controlling the voiding. For an open via situation, a full thermal pad is desired for a low number of via. For a large number of via, a divided thermal pad is preferred due to better venting capability. Placement of a via at the perimeter prevents voiding caused by via. A wider venting channel has a negligible effect on voiding and reduces joint continuity. For divided thermal pad, the SMD system is more favorable than the NSMD system, with the latter suffering more voiding due to a thinner solder joint and possibly board outgassing. Performance of a divided thermal pad is dictated by venting accessibility, not by the shape. Voiding reduction increases with increasing venting accessibility, although introduction of a channel area compromises the continuity of solder joint. Reduced solder paste volume causes more voiding. Short profiles and long hot profiles are most promising in reducing the voiding. Voiding behavior of a QFN is similar to typical SMT voiding and increases with pad oxidation and further reflow.

Key words: QFN, void, solder, SMT, reflow, assembly

INTRODUCTION

Quad Flat No Leads (QFN) package designs are receiving more and more attention in electronics industry. This package offers a number of benefits including (1) small size,

such as a near die-sized footprint, thin profile, and light weight; (2) easy PCB trace routing due to the use of perimeter I/O pads; (3) reduced lead inductance; and (4)

good thermal and electrical performance due to the adoption of exposed copper die-pad technology. These features make the QFN an ideal choice for many new applications where size, weight, electrical, and thermal properties are important. However, adoption of QFN often runs into voiding issue during SMT assembly. Upon reflow, outgassing of solder paste flux at the large thermal pad has difficulty escaping and inevitably results in voiding [1]. It is well known that the presence of voids will affect the mechanical properties of joints and deteriorate the strength, ductility, creep, and fatigue life [2, 3, and 4]. In addition, voids could also produce spot overheating, lessening the reliability of joints. This is a particular concern for QFN where the primary function of thermal pads is for heat dissipation. In this study, various designs of thermal pads, stencil patterns, and reflow profiles are evaluated in order to identify the optimal condition for minimizing the voiding. The effect of each variable on voiding is analyzed and presented in the paper.

EXPERIMENTAL DESIGN

In this work, a dummy QFN component A-MLF68-10mm-0.5mm-DC-Sn was used with 68 peripheral pads, 10 mm long on each side, 0.5mm pitch, daisy-chained, with a Sn surface finish, as shown in Fig. 1.

Figure 1. QFN component used for voiding study.

The primary focus for voiding control is the thermal pad design on FR-4 test board, including (1) a venting channel through the solder mask at the peripheral of the thermal pad; (2) the number of microvia on the thermal pad; (3) a solder mask versus a venting channel when dividing the thermal pad; and (4) the number and shape of divided thermal pads. Impact of the solder paste volume is controlled by regulating the stencil aperture size. The effect of a soldering profile and heat history is also examined. All parameters involved are shown in Table 1.

Table 1. Parameters used in voiding study

Parameter	Sub parameter	Layers
Thermal Pad on PCB	Microvia number	0, 16, 32, 36
	Peripheral venting for full thermal pad	With and without
	Dividing method	Solder mask, venting channel
	Thermal subpad shape	Square, triangle
	Thermal subpad number	1, 4, 8, 9
Stencil	Aperture	85%, 100%
Heat History	Reflow profile	Short, long cool, long, long hot
	Other heat treatment	Prebake, 1 reflow, 2 reflow

Table 2 shows the design of various thermal pads on a test board. The dimension of a full thermal pad is identical to that of the QFN. The surface finish for all pads, depicted in red, on the test board is immersion silver. Fig. 2 shows the layout of the test board.

Table 2. Design of thermal pads on test board.

Full, no vent, 36 via	Full, vented, 36 via	Full, no vent, 16 via
Full, vented, 16 via	Square 4, 16 via	Triangle 4, 16 via
Square 9, 36 via, NSMD	Square 9, 36 via, SMD	Triangle 8, 32 via

EXPERIMENTAL PROCEDURE

A no-clean solder paste with 88.5% SAC305 with type 4 metal load was used for assembly of the QFN. For the test, the solder paste was printed through a stencil with 125 micron thickness onto the test board. The aperture design is 1:1, unless otherwise specified. The QFN components were then placed and sent through a BTU oven with air atmosphere. Four reflow profiles were used, short, long cool, long, and long hot, as shown in Figure 3.

Figure 2. Layout of test board

To simulate the soldering conditions of a double-sided board, the voiding performance of the following two conditions were also checked. In one instance, the board was prebaked by sending the board through an oven prior to printing the solder paste. In another, the printed board was reflowed twice.

VOIDING ASSESSMENT

The voiding performance was determined with X-ray, as shown in Figure 4 for designs with a 0.22mm wide channel and reflowed with a long hot profile, and in Figure 5 for designs with a 0.33mm wide channel and reflowed using a long cool profile. The drastic difference in voiding behavior between the two sets demonstrates the tremendous impact of design and process conditions. Three properties are determined, as defined in Table 3. For some solder joints, cross-sectioning was also conducted in order to elucidate the characteristics of voiding.

Table 3. Definition of three voiding properties.

Property	Definition
Discontinuity	Percentage of area under the QFN thermal pad where the vertical metal continuity from QFN to PCB surface is interrupted
Void Average	Average of multiple QFNs for void area percentage within the metallic pad of QFN
Largest Void	The largest void measured for a category of QFN joints

RESULTS

1. Individual Data Set

The individual data set for each of the test conditions are shown in Figure 6. A couple trends can be noticed quickly. Dividing the thermal pads into sub-units results in an abrupt drop in the largest void. In the meantime, the presence of a channel area also results in an increase in discontinuity, as reflected by the raised height of the average void plus the channel area. Apparently, the immediate effect of dividing the thermal pad is a reduction in the uncontrollable, harmful

large voids, replacing it with a controlled, even distribution of discontinuity. The discontinuity of the latter may be equal or higher than the former.

2. Effect of the Number of Via

Via is a direct contributor to voiding, mainly due to the presence of a dead corner where the entrapped flux cannot escape at the solder coalescence stage [5, 6]. This can be easily noticed in Figure 4 and 5 where the propensity of voids at via locations is particularly high for full pad solder joints. Accordingly, the voiding extent will be expected to increase with an increasing number of via. This is exactly

what was observed in this study when reflowed using a long hot profile, as shown in Figure 7. When the via number is high, the discontinuity of a full pad becomes comparable with that of a divided pad, and the sporadic occurrence of large voids becomes a distinct disadvantage of the full pad design, as evidenced in Figure 6.

Since a high number of via is desired for efficient heat dissipation, the best option will be to plug the via with a solderable material, such as plated copper.

The number of via bears no relation with voiding for divided pads, as evidenced in Figure 4 and 5. This is attributed to the peripheral location of via for those divided pads. Although flux may still get entrapped in those via, outgassing does not form voids easily due to the easy escape of volatiles [7].

If plugging the via is not an option, based on the benign impact of peripheral via for divided pads, it is advisable to design the via on a full pad at peripheral locations whenever possible.

3. Effect of Peripheral Venting

The peripheral venting channel on a solder mask around the full pad was designed to facilitate outgassing, since the bottom of the QFN is nearly sitting on the top of board surface. Figure 8 shows that peripheral venting does reduce the size of the largest void on full pads. The effect appears to be moderate. When examining the void average, the effect of peripheral venting appears to be insignificant.

Table 4. Calculated venting accessibility of thermal pad designs

Thermal pad design	Venting accessibility
Full pad	4

Effect of Venting Channel Width on Voiding

Figure 9. Effect of the venting channel width on average voiding behavior of all profiles

Effect of Venting Accessibility on Largest Void (ImAg, 0.22 mm Channel)

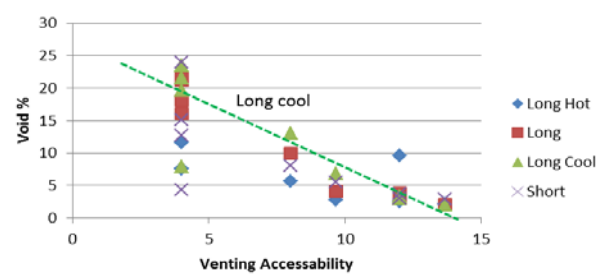

Figure 10. Effect of venting accessibility on void average

Presumably, the additional venting capability due to a peripheral venting channel is negligible when compared with the clearance between the QFN and the board surface.

4. Effect of Venting Channel Width

When examining Figure 4, solder bridges across the venting channel was observed for a 0.22mm wide channel. It is unclear whether these solder bridges will obstruct the outgassing significantly, thus affecting the voiding extent.

Figure 11. Effect of venting accessibility on largest void

Figure 12. Effect of venting accessibility on discontinuity

Figure 13. Effect of a solder mask (SMD) or venting channel (NSMD) on void average.

Figure 9 compares the average voiding behavior of all profiles for venting channels with 0.22mm and 0.33 mm widths. An increase in channel width has no effect on the voiding average, but does cause a net increase in the channel area, and consequently an increase in discontinuity.

5. Effect of Venting Accessibility

Theoretically, the closer the outgassing is to an open space or a venting channel, the less chance for a void to be developed. This venting accessibility can be defined as perimeter length per unit area of metal pad. Table 4 shows the calculated venting accessibility of various thermal pad designs.

Figure 14. Comparison of the solder layer thickness for NSMD (venting channel) and SMD systems.

Figure 15. Cross-section of a venting channel of an SMD system (left) and a NSMD system (right).

Figure 16. Effect of solder paste volume on void average.

With increasing venting accessibility, the void average and largest void decrease readily, especially for the long cool profile, as shown in Figures 10 and 11, respectively. However, the advantage voiding reduction is offset by the increase in discontinuity, particularly for the short profile, as shown in Figure 12. For a long cool profile, the discontinuity increases only moderately with increasing venting accessibility. In other words, when the voiding is a major threat, such as designs with a high number of vias, or when a short profile is not a viable option, then a venting channel design becomes a favorable choice. Although some data scattering still exists, the venting accessibility concept allows engineers to design thermal pads with a minimal need of empirical run.

6. Solder Mask Defined versus Non-Solder Mask Defined

Solder does not wet onto either the solder mask or FR-4 between thermal pads. Wherever there is no solder, there is opportunity for venting. Based on the venting accessibility discussed in the previous session, a thermal pad divided by

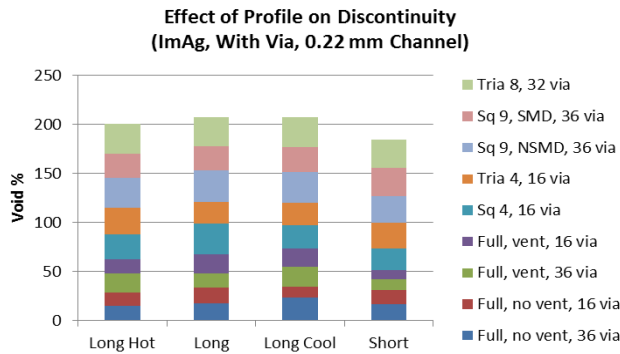

Figure 17. Effect of profile on discontinuity.

Figure 19. Effect of profile on largest void.

Figure 18. Effect of profile on void average.

either a solder mask or a venting channel on FR-4 are expected to have similar effects on voiding. However, when comparing Square 9 (SMD) with Square 9 (NSMD) designs, the void average of NSMD (venting channel design) is quite a bit higher than the SMD design, as shown in Figures 6 and 13.

The unexpectedly high void average performance of NSMD system can be attributed partly to its thinner solder joint, as shown in Figure 14. The solder joint thickness measured is 63μ and 79μ for NSMD and SMD system, respectively. A thinner solder joint would have a greater difficulty for the void to escape [1, 8]. The thicker solder joint for an SMD system is attributable to the higher solder paste volume deposited due to the presence of a solder mask at printing. The thickness of the solder mask measured is about 21μ . However, this thickness factor is considered, at best, a secondary factor.

Another factor, which could be the primary factor contributing to the high voiding of a NSMD system, is the outgassing of FR-4 during reflow. With the venting channel frequently blocked by the solder bridges, volatiles from FR-4 can not be vented readily and, consequently, result in more voiding under QFN. In the event of an SMD system, the solder joint is totally separated from FR-4 and thus is not affected by any FR-4 outgassing.

Use of an SMD system may have a higher value in largest void than a NSMD system, when comparing Square 9

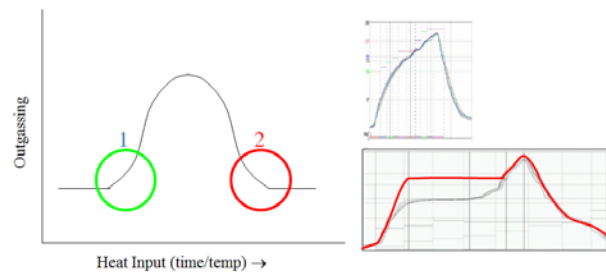

Figure 20. Relation between heat input and outgassing.

(SMD) and Square 9 (NSMD) in Figure 6. This may be caused by the partially blocked venting path due to the presence of solder mask, as shown in Figure 5. For a NSMD system, the venting channel is fairly open, even in the presence of a solder bridge.

Overall, the SMD system appears to be a better design than the NSMD system, in terms of reducing voiding.

7. Solder Paste Volume Effect

The effect of solder paste volume is controlled by the stencil aperture size. An aperture dimension of 1:1 is compared with an 85% opening, as shown in Figure 16. A moderately adverse effect of a smaller aperture opening is observed. Presumably, this can also be attributed to the thinner solder joints caused by a reduced solder paste volume, as discussed in the previous session.

8. Effect of Reflow Profile

The effect of a reflow profile on voiding is shown in Figures 17, 18, and 19. Overall, both short and long hot profiles rendered lower voiding than the other profiles in between. The short profile is preferred for a low void average, while the long hot profile is better for reducing the largest void.

The favorable voiding behavior of short and long hot profiles can be explained by the outgassing diagram shown in Figure 20. In general, all fluxes outgas upon heating. The outgassing increases with increasing heat input, whether it is due to an increase in temperature or time. Eventually, the volatiles get depleted, and the outgassing decreases with a further increase in heat input. For fluxes, the solvents

Figure 21. Effect of prebake on void average.

usually vaporize during an early heating stage, followed by the volatile solids getting vaporized at a higher temperature.

Voiding in solder joints occur when volatiles are generated from the interior of a solder joint when the solder is at molten state. In order to minimize the outgassing at soldering temperatures, the outgassing rate should be minimized at temperatures above liquidus. This can be accomplished through two approaches. First, heat the flux quickly to a temperature slightly above the melting temperature, then cool down rapidly before the volatile solids get a chance to vaporize. This corresponds to zone 1 on the diagram and can be exemplified by the upper profile on the right. Second, bring the flux to a temperature right below the melting temperature of solder, hold at that temperature until most of the volatiles are gone, then bring the flux to slightly above the melting temperature, followed by rapid cooling. This corresponds to zone 2, and can be exemplified by the lower profile on the right.

In this work, the short profile reflects the zone 1 approach, while the long hot profile reflects the zone 2 approach. Long cool and long profiles may reflect the rapid outgassing region between zones 1 and 2, thus render more voiding than both short and long hot profiles.

9. Effect of Prebake

Prebaking is conducted by sending the bare test boards through the reflow oven set at a short profile. The boards are then printed with solder paste, followed by QFN placement and reflow, again using the short profile. Figure 21 shows that the prebaked boards exhibit a higher void average than the fresh boards. This increase in voiding caused by the pad oxidation at prebaking indicates that, similar to voiding phenomena associated with other SMT component assemblies, a surface finish robust against oxidation will be beneficial when attempting to control voiding of QFN for a double sided board.

10. Effect of Double Reflow

A double reflow results in a higher void average, as shown in Figure 22. Apparently, this is attributable to the additional outgassing at the second reflow and is fairly

Figure 22. Effect of double reflow on void average.

similar to voiding behavior experienced with typical SMT assembly processes.

CONCLUSION

Thermal pad voiding control at QFN assembly is a major challenge due to the large coverage area, large number of via, and low standoff. Both design and process were studied for minimizing and controlling the voiding. Eliminating the via by plugging is most effective in reducing the voiding. For open via situations, a full thermal pad is desired for a low number of via. For a high number of via, a divided thermal pad is preferred due to better venting capability. Placement of via at the perimeter prevents voiding caused by via. A wider venting channel has a negligible effect on voiding and reduces joint continuity. For divided thermal pads, an SMD system is more favorable than a NSMD system, with the latter suffering more voiding due to a thinner solder joint and possibly board outgassing. Performance of a divided thermal pad is dictated by venting accessibility not by the shape. Voiding reduction increases with increasing venting accessibility, although the introduction of a channel area compromises the continuity of the solder joint. Reduced solder paste volume causes more voiding. Short and long hot profiles are most promising in reducing the voiding. Voiding behavior of QFN is similar to typical SMT voiding and increases with pad oxidation and further reflow.
